Remark: $\boldsymbol{A} \times \boldsymbol{B}=-\boldsymbol{B} \times \boldsymbol{A}, \boldsymbol{A} \times \boldsymbol{A}=0$.
Application of cross product: equation of plane through $P_{1}, P_{2}, P_{3}: P=(x, y, z)$ is in the plane iff $\operatorname{det}\left(\overrightarrow{P_{1} P} P, \overrightarrow{P_{1} P_{2}}, \overrightarrow{P_{1} P_{3}}\right)=0$, or equivalently, $\overrightarrow{P_{1} P} \cdot \boldsymbol{N}=0$, where $\boldsymbol{N}$ is the normal vector $N=\overrightarrow{P_{1} P_{2}} \times \overrightarrow{P_{1} P_{3}}$. I explained this geometrically, and showed how we get the same equation both ways.

Matrices. Often quantities are related by linear transformations; e.g. changing coordinate systems, from $P=\left(x_{1}, x_{2}, x_{3}\right)$ to something more adapted to the problem, with new coordinates $\left(u_{1}, u_{2}, u_{3}\right)$. For example

$$
\left\{\begin{array}{l}
u_{1}=2 x_{1}+3 x_{2}+3 x_{3} \\
u_{2}=2 x_{1}+4 x_{2}+5 x_{3} \\
u_{3}=x_{1}+x_{2}+2 x_{3}
\end{array}\right.
$$

Rewrite using matrix product: $\left[\begin{array}{lll}2 & 3 & 3 \\ 2 & 4 & 5 \\ 1 & 1 & 2\end{array}\right]\left[\begin{array}{l}x_{1} \\ x_{2} \\ x_{3}\end{array}\right]=\left[\begin{array}{l}u_{1} \\ u_{2} \\ u_{3}\end{array}\right]$, i.e. $A X=U$.
Entries in the matrix product $=\operatorname{dot}$ product between rows of $A$ and columns of $X$. (here we multiply a $3 \times 3$ matrix by a column vector $=3 \times 1$ matrix).

More generally, matrix multiplication $A B$ :

$$
\left[\begin{array}{cccc}
1 & 2 & 3 & 4 \\
\cdot & \cdot & \cdot & \cdot \\
\cdot & \cdot & \cdot & \cdot
\end{array}\right]\left[\begin{array}{ll}
\cdot & 0 \\
\cdot & 3 \\
\cdot & 0 \\
\cdot & 2
\end{array}\right]=\left[\begin{array}{cc}
\cdot & 14 \\
\cdot & \cdot \\
\cdot & \cdot
\end{array}\right]
$$

(Also explained one can set up $A$ to the left, $B$ to the top, then each entry of $A B=\operatorname{dot}$ product between row to its left and column above it).

Note: for this to make sense, width of $A$ must equal height of $B$.
What $A B$ means: $B X=$ apply transformation $B$ to vector $X$, so $(A B) X=A(B X)=$ apply first $B$ then $A$. (so matrix multiplication is like composing transformations, but from right to left!)
(Remark: matrix product is not commutative, $A B$ is in general not the same as $B A$ - one of the two need not even make sense if sizes not compatible).

Identity matrix: identity transformation $I X=X . \quad I_{3 \times 3}=\left[\begin{array}{ccc}1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1\end{array}\right]$
Example: $R=\left[\begin{array}{cc}0 & -1 \\ 1 & 0\end{array}\right]=$ plane rotation by 90 degrees counterclockwise.
$R \hat{\imath}=\hat{\boldsymbol{\jmath}}, R \hat{\boldsymbol{\jmath}}=-\hat{\boldsymbol{\imath}}, R^{2}=-I$.
Inverse matrix. Inverse of a matrix $A$ (necessarily square) is a matrix $M=A^{-1}$ such that $A M=M A=I_{n}$.
$A^{-1}$ corresponds to the reciprocal linear relation.
E.g., solution to linear system $A X=U$ : can solve for $X$ as function of $U$ by $X=A^{-1} U$.

Cofactor method to find $A^{-1}$ (efficient for small matrices; for large matrices computer software uses other algorithms): $A^{-1}=\frac{1}{\operatorname{det}(A)} \operatorname{adj}(A)(\operatorname{adj}(A)=$ "adjoint matrix" $)$.

Illustration on example: starting from $A=\left[\begin{array}{lll}2 & 3 & 3 \\ 2 & 4 & 5 \\ 1 & 1 & 2\end{array}\right]$

1) matrix of minors ( $=$ determinants formed by deleting one row and one column from $A$ ): $\left[\begin{array}{rrr}3 & -1 & -2 \\ 3 & 1 & -1 \\ 3 & 4 & 2\end{array}\right]$ (e.g. top-left is $\left.\left|\begin{array}{ll}4 & 5 \\ 1 & 2\end{array}\right|=3\right)$.
2) cofactors $=$ flip signs according to checkerboard diagram \begin{tabular}{lll}
\& + \& - \\

- \& + \& + \\
\& + \& - \\
\hline
\end{tabular} : get \(\left[\begin{array}{rrr}3 \& +1 \& -2 \\

-3 \& 1 \& +1 \\
3 \& -4 \& 2\end{array}\right]\)
3) transpose $=$ exchange rows $/$ columns (read horizontally, write vertically) get the adjoint $\operatorname{matrix} M^{T}=\operatorname{adj}(A)=\left[\begin{array}{rrr}3 & -3 & 3 \\ 1 & 1 & -4 \\ -2 & 1 & 2\end{array}\right]$
4) divide by $\operatorname{det}(A)($ here $=3)$ : get $A^{-1}=\frac{1}{3}\left[\begin{array}{rrr}3 & -3 & 3 \\ 1 & 1 & -4 \\ -2 & 1 & 2\end{array}\right]$.
18.02 Lecture 4. - Thu, Sept 13, 2007

Handouts: PS1 solutions; PS2.
Equations of planes. Recall an equation of the form $a x+b y+c z=d$ defines a plane.

1) plane through origin with normal vector $\boldsymbol{N}=\langle 1,5,10\rangle: P=(x, y, z)$ is in the plane $\Leftrightarrow$ $\boldsymbol{N} \cdot \overrightarrow{O P}=0 \Leftrightarrow\langle 1,5,10\rangle \cdot\langle x, y, z\rangle=x+5 y+10 z=0$. Coefficients of the equation are the components of the normal vector.
2) plane through $P_{0}=(2,1,-1)$ with same normal vector $\boldsymbol{N}=\langle 1,5,10\rangle$ : parallel to the previous one! $P$ is in the plane $\Leftrightarrow \boldsymbol{N} \cdot \overrightarrow{P_{0} P}=0 \Leftrightarrow(x-2)+5(y-1)+10(z+1)=0$, or $x+5 y+10 z=-3$. Again coefficients of equation $=$ components of normal vector.
(Note: the equation multiplied by a constant still defines the same plane).
So, to find the equation of a plane, we really need to look for the normal vector $\boldsymbol{N}$; we can e.g. find it by cross-product of 2 vectors that are in the plane.

Flashcard question: the vector $\boldsymbol{v}=\langle 1,2,-1\rangle$ and the plane $x+y+3 z=5$ are 1) parallel, 2) perpendicular, 3) neither?
(A perpendicular vector would be proportional to the coefficients, i.e. to $\langle 1,1,3\rangle$; let's test if it's in the plane: equivalent to being $\perp \boldsymbol{N}$. We have $\boldsymbol{v} \cdot \boldsymbol{N}=1+2-3=0$ so $\boldsymbol{v}$ is parallel to the plane.)

Interpretation of $\mathbf{3 x} \mathbf{3}$ systems. A $3 x 3$ system asks for the intersection of 3 planes. Two planes intersect in a line, and usually the third plane intersects it in a single point (picture shown). The unique solution to $A X=B$ is given by $X=A^{-1} B$.

Exception: if the 3rd plane is parallel to the line of intersection of the first two? What can happen? (asked on flashcards for possibilities).

If the line $\mathcal{P}_{1} \cap \mathcal{P}_{2}$ is contained in $\mathcal{P}_{3}$ there are infinitely many solutions (the line); if it is parallel to $\mathcal{P}_{3}$ there are no solutions. (could also get a plane of solutions if all three equations are the same)

These special cases correspond to systems with $\operatorname{det}(A)=0$. Then we can't invert $A$ to solve the system: recall $A^{-1}=\frac{1}{\operatorname{det}(A)} \operatorname{adj}(A)$. Theorem: $A$ is invertible $\Leftrightarrow \operatorname{det} A \neq 0$.

Homogeneous systems: $A X=0$. Then all 3 planes pass through the origin, so there is the obvious ("trivial") solution $X=0$. If $\operatorname{det} A \neq 0$ then this solution is unique: $X=A^{-1} 0=0$. Otherwise, if $\operatorname{det} A=0$ there are infinitely many solutions (forming a line or a plane).

Note: $\operatorname{det} A=0$ means $\operatorname{det}\left(\boldsymbol{N}_{1}, \boldsymbol{N}_{2}, \boldsymbol{N}_{3}\right)=0$, where $\boldsymbol{N}_{i}$ are the normals to the planes $\mathcal{P}_{i}$. This means the parallelepiped formed by the $\boldsymbol{N}_{i}$ has no area, i.e. they are coplanar (showed picture of 3 planes intersecting in a line, and their coplanar normals). The line of solutions is then perpendicular to the plane containing $\boldsymbol{N}_{i}$. For example we can get a vector along the line of intersection by taking a cross-product $N_{1} \times \boldsymbol{N}_{2}$.

General systems: $A X=B$ : compared to $A X=0$, all the planes are shifted to parallel positions from their initial ones. If $\operatorname{det} A \neq 0$ then unique solution is $X=A^{-1} B$. If $\operatorname{det} A=0$, either there are infinitely many solutions or there are no solutions.
(We don't have tools to decide whether it's infinitely many or none, although elimination will let us find out).

### 18.02 Lecture 5. - Fri, Sept 14, 2007

Lines. We've seen a line as intersection of 2 planes. Other representation $=$ parametric equation $=$ as trajectory of a moving point.
E.g. line through $Q_{0}=(-1,2,2), Q_{1}=(1,3,-1)$ : moving point $Q(t)$ starts at $Q_{0}$ at $t=0$, moves at constant speed along line, reaches $Q_{1}$ at $t=1$ : its "velocity" is $\vec{v}=\overrightarrow{Q_{0} Q_{1}} ; \overrightarrow{Q_{0} Q(t)}=t \overrightarrow{Q_{0} Q_{1}}$. On example: $\langle x+1, y-2, z-2\rangle=t\langle 2,1,-3\rangle$, i.e.

$$
\left\{\begin{array}{l}
x(t)=-1+2 t \\
y(t)=2+t \\
z(t)=2-3 t
\end{array}\right.
$$

Lines and planes. Understand where lines and planes intersect.
Flashcard question: relative positions of $Q_{0}, Q_{1}$ with respect to plane $x+2 y+4 z=7$ ? (same side, opposite sides, one is in the plane, can't tell).
(A sizeable number of students erroneously answered that one is in the plane.)
Answer: plug coordinates into equation of plane: at $Q_{0}, x+2 y+4 z=11>7$; at $Q_{1}, x+2 y+4 z=$ $3<7$; so opposite sides.

Intersection of line $Q_{0} Q_{1}$ with plane? When does the moving point $Q(t)$ lie in the plane? Check: at $Q(t), x+2 y+4 z=(-1+2 t)+2(2+t)+4(2-3 t)=11-8 t$, so condition is $11-8 t=7$, or $t=1 / 2$. Intersection point: $Q\left(t=\frac{1}{2}\right)=(0,5 / 2,1 / 2)$.
( W hat would happen if the line was parallel to the plane, or inside it. Answer: when plugging the coordinates of $Q(t)$ into the plane equation we'd get a constant, equal to 7 if the line is contained in the plane - so all values of $t$ are solutions - or to something else if the line is parallel to the plane - so there are no solutions.)

## General parametric curves.

Example: cycloid: wheel rolling on floor, motion of a point $P$ on the rim. (Drew picture, then showed an applet illustrating the motion and plotting the cycloid).

Position of $P$ ? Choice of parameter: e.g., $\theta$, the angle the wheel has turned since initial position. Distance wheel has travelled is equal to arclength on circumference of the circle $=a \theta$.

Setup: $x$-axis $=$ floor, initial position of $P=$ origin; introduce $A=$ point of contact of wheel on floor, $B=$ center of wheel. Decompose $\overrightarrow{O P}=\overrightarrow{O A}+\overrightarrow{A B}+\overrightarrow{B P}$.
$\overrightarrow{O A}=\langle a \theta, 0\rangle ; \overrightarrow{A B}=\langle 0, a\rangle$. Length of $\overrightarrow{B P}$ is $a$, and direction is $\theta$ from the $(-y)$-axis, so $\overrightarrow{B P}=\langle-a \sin \theta,-a \cos \theta\rangle$. Hence the position vector is $\overrightarrow{O P}=\langle a \theta-a \sin \theta, a-a \cos \theta\rangle$.

Q: What happens near bottom point? (flashcards: corner point with finite slopes on left and right; looped curve; smooth graph with horizontal tangent; vertical tangent (cusp)).

Answer: use Taylor approximation: for $t \rightarrow 0, f(t) \approx f(0)+t f^{\prime}(0)+\frac{1}{2} t^{2} f^{\prime \prime}(0)+\frac{1}{6} t^{3} f^{\prime \prime \prime}(0)+\ldots$. This gives $\sin \theta \approx \theta-\theta^{3} / 6$ and $\cos \theta \approx 1-\theta^{2} / 2$. So $x(\theta) \simeq \theta^{3} / 6, y(\theta) \simeq \theta^{2} / 2$ Hence for $\theta \rightarrow 0$, $y / x \simeq\left(\frac{1}{2} \theta^{2}\right) /\left(\frac{1}{6} \theta^{3}\right)=3 / \theta \rightarrow \infty:$ vertical tangent.
